ABSTRACT

5G will require a number of key technological components to meet its very ambitious goals, including Heterogeneous Networks and Small Cells. The Dense Deployment of SBSs will play a major role as they can be installed in a more targeted manner to relieve traffic in hot spot areas, increase coverage, and spectral efficiency. However, the current deployment of the SBS is static, normally deployed on demand around hotspots. In the scenario of unpredictable crowd movement, these static deployment of small cells can be inefficient with high CAPEX and OPEX. This project focuses on the scenario where UE-based Virtual Base Stations can be dynamically selected among UEs to deal effectively with the non-stationary, non-uniform distribution of mobile traffic with respect to time and space domain. To implement this concept, we propose an efficient clustering technique (K-means Clustering) and communication parameters such as received power, battery discharge rate and outage probability to select the best set of UE-VBSs to supplement an overlay loaded SBS. Throughput is used to compare the performance of our selection algorithm, against the performance of a random selection algorithm. Simulations yields results which highlights salient features of the algorithm, as well as its limitations with regard to scalability. The algorithm is simulated and evaluated in MATLAB.

CHAPTER 1

INTRODUCTION

1.1 INTRODUCTION

5G being the next generation of cellular network, has ambitious set of goals. It aims to achieve low energy consumption, high system spectral efficiency, very high bit rates, lower delays better coverage, and a higher number of connected devices. To meet these key communication features of 5G, the dense deployment of SBSs is expected to play a major role. [1] A SBS can serve as a BS to the UEs in a small neighborhood in its proximity, thereby increasing the range of communication without compromising the data rate and other key parameters mentioned below. Small Cells are the primary driver of growth in the overall 5G RAN market. Normally, the deployment of the SBS is static. Small Cells reduce the physical separation between the UEs and the BS, which leads to: i) higher data rates and throughput; ii) increased spectral efficiency and higher capacity; iii) reduced energy; and iv) enable the minimization of power emitted by both the UEs and the BSs. Small Cells are bringing huge amount of capacity and data rates in areas where it is needed the most. However, a major technical concern for 5G networks is its static deployment, making them inflexible to cope with the changing (short term) dynamics of mobile traffic. The mobile traffic is not always uniformly and symmetrically distributed in both spatial and time domains due to the dynamic activity and mobility of the human factor. It shifts with the mobile user population activities that change through time. To cope with the mobile traffic dynamics in Ultra-Dense 5G network, a UE-based virtual BS as a solution is proposed, that provides for a real time and dynamic deployment of virtual BSs in a flexible manner. A group of UEs acts as UE-VBSs with BS functionalities to facilitate the networking

requirements of other UEs at any time and any location. Hence, this solution removes the restraints of existing Small Cells beyond their static positioning.

Fig. 1.1 Small cell Network with UE VBS-

Network consisting of one BS where active UE-VBSs are the Black Nodes and UEs are the White Nodes.

To illustrate our ideas, a simple scenario of a network consisting of one BS and eight active UE-VBSs is depicted in Fig. 1. In this scenario, a BS needs to serve a number of UEs. However, the BS does not have the capacity to meet their requirements in terms of number of connections or bandwidth. To minimize the heavy load traffic problem, it is proposed that the BS can select a subset of the UEs served by the BS so as to serve a small neighborhood in their proximity by becoming UE-VBSs. These UE-VBSs are served by the BS and they in turn serve a number of UEs in their proximity. This project primarily focusses on the selection of UE-VBS by first forming clusters using a suitable clustering algorithm and then choosing one UE to act as a VBS for all the nodes in that cluster for a particular time instance t . The allocation of a UE to act as a VBS is dynamic and time-varying as the UEs are all mobile nodes.

1.2 MOTIVATION AND OBJECTIVES

Even though 5G has higher data rate, higher capacity, higher QoS among many communication parameters, when compared to 4G, the range of communication of 5G is much lesser (uses FR1 band of frequencies). This is a major problem and should be improved for efficient communication. Therefore, a major paradigm shift is to be adopted. Small cells and ultra-dense networks will be deployed to make the network more flexible and to provide more users with network connectivity anywhere and anytime. These deployments are static but the UE nodes are mobile and thus a dynamic allocation is extremely important for the communication system to work with full efficiency.

The objectives of the proposed model are as follows:

- To position the UEs with pseudo random 2D Cartesian coordinate pairs.
- To compute battery discharge rate for each UE in the cell.
- To determine best cluster size for a given small cell with multiple UEs.
- To organize each UE into a cluster by using a suitable clustering algorithm.
- To measure Power received using log-normal path loss.
- To choose eligible UEs from each cluster to act as a VBS based on Power received and battery discharge rate.
- To determine SINR for each eligible UE VBS and select eligible UE with maximum SINR to act as UE VBS.
- To measure Throughput and compare the results with LTE, NR without algorithm and NR with algorithm.

1.3 ORGANISATION OF THESIS

The remainder of the thesis is divided into chapters based on the following:

Chapter 2 deals with literature survey pertaining to ‘Selection of UE Virtual Small cells using affinity propagation clustering’ and ‘LEACH based energy efficient routing protocol for WSN’, ‘An optimized clustering algorithm for mobile ADHOC networks’ and ‘Outage probability for Multi-hop D2D communications with shortest path routing’.

Chapter 3 explains the current model of 5G and what are the drawbacks related to it and why it is essential to adopt to UE-VBS allocation algorithm.

Chapter 4 presents multiple clustering algorithms, the parameters and metrics considered for each and why K-means clustering is considered for the UE-VBS selection.

Chapter 5 deals with the different communication parameters used for the selection of UE VBS and its importance for the same.

Chapter 6 explains the methodology of implementation and highlights the advantages of the selection algorithm.

Chapter 7 presents the experimental results obtained upon testing the algorithm.

Finally, Chapter 8 summarizes the entire thesis and also outlines possible future extensions.

CHAPTER 2

LITERATURE REVIEW

Our system aims to produce an UE based Virtual Base Station network in a 5G cell. Research is being extensively conducted in this area of 5G. We have listed some of those earlier researches below. While some of them are not directly based on 5G, they do provide an insight into multi hop communication which is slightly analogous to UE VBS communication.

2.1 SELECTION OF UE- VIRTUAL SMALL CELL BASE STATIONS USING AFFINITY PROPAGATION CLUSTERING

Christophoros Christophorou et al (2018) have dealt with the concept of selecting an UE VBS through the prism of received power of an UE from an eligible UE VBS, alone. The authors have taken a message passing approach to selecting the UE VBS whereas, our research uses a path loss model and a probabilistic approach.

2.2 LEACH BASED ENERGY EFFICIENT ROUTING PROTOCOL FOR WIRELESS SENSOR NETWORKS

Alka Singh et al (2016) used a multi-hop LEACH routing protocol in wireless Sensor networks. The purpose of this research is to minimize energy dissipation in the transmission from cluster head to the base station. Multi-hop communication has been used for this purpose. In our research, a similar approach has been taken wherein the communication from the BS to UE VBS to UE is considered a multi hop communication.

2.3 AN OPTIMIZED CLUSTERING ALGORITHM FOR MOBILE AND ADHOC NETWORKS

S.Pathak et al (2017) considered the battery level of the UE to split the UEs into several clusters. In this research, the author has implemented the algorithm for AdHoc networks, whereas we have used it as one of the parameters in 5G networks for clustering purposes.

2.4 OUTAGE PROBABILITY FOR MULTI-HOP D2D COMMUNICATIONS WITH SHORTEST PATH ROUTING

Siyi Wang et al (2015) provides a tractable theoretical framework for analysing the performance of D2D communications. In our research, we use the SINR and Outage Probability formulae proposed in this literature to be used as one of the parameters in selecting the UE VBS.

CHAPTER 3

REQUIREMENTS FOR 5G

In conventional cellular networks, mobile phones were practically the only type of device expected to be supported. With the proliferation of Internet and its numerous applications, there was the problem of handling several classes of traffic to meet the different QoS requirements of diverse applications like video streaming, data, etc. A similar situation is arising now with the need to support several types of devices and applications with drastically varying QoS requirement to provide better experience to the user. Unlike previous generations of cellular networks, 5G cellular network is envisioned to support a multitude of devices and applications like smartwatches,

autonomous vehicles, Internet of Things (IoT), and tactile Internet. In particular, according to the International Telecommunication Union (ITU), there are three types of service scenarios to be supported in 5G, which are mobile broadband services, massive machine type communications, and ultra-reliable and low latency communications, respectively. The various types of devices and application scenarios need more sophisticated networks that not only can support high throughput, but also provide low latency in data delivery, efficient energy consumption scheme, high scalability to accommodate a large number of devices, and ubiquitous connectivity for users. These requirements are described and how they can be met by potential solutions are explained below.

3.1 HIGH DATA RATES

The metric of data rate has been the most important evaluation factor over generations of wireless communication networks. With the advent of mobile Internet and services such as high-definition (HD) video streaming, pervasive video and video sharing, virtual reality available on mobile phones, as well as the proliferation of tablets and laptops which are accessible to wireless networks, increasing the data rate of cellular network is becoming an inevitable market driving force. Although the current maximum data rates can support HD video streaming which requires 8–15 Mbps, there are applications like ultra-HD 4K video streaming, high-definition gaming, and 3D contents, which require even higher data rates at around 25 Mbps to provide a satisfactory experience to users. With these emerging applications demanding higher data rates, 5G networks are expected to have the peak data rate of around 10 Gbps which is a 100-fold improvement over current 4G networks. Besides increasing the maximum data rate, the cell-edge data rate, as the worst-case data rate users experience, should also be improved to 100 Mbps, which is a 100 times

improvement over 4G networks at cell edge. The maximum data rate is an optimum estimate that a user can experience. In fact, the effects of intercell interference and transmission loss make the maximum value hardly achievable. Therefore, edge data rate level becomes more important from the perspective of network engineering, as this data rate must support around 95% of users connected to the network. Another metric based on data rate that characterizes the network is the area capacity, which specifies the total data rate the network can serve per unit area. According to its definition, the unit of area capacity is normally bits per second per unit area. This metric is expected to increase 100 times in 5G compared to 4G network. This demand for increase in data rate can be met by techniques such as millimeter wave communications, massive MIMO systems, and wireless software-defined networking, etc.

3.2 LOW LATENCY

The roundtrip latency of data plane in the LTE network is around 15 milliseconds (ms). However, for the recently emerging applications such as tactile Internet, virtual reality, and multiplayer gaming that 5G networks are expected to support, the latency should be upgraded to an order of magnitude faster than current network, at around 1 ms. For instance, tactile Internet is a recently developed application where the wireless network is used for real-time control applications. The latency required for such applications is determined by the typical interaction for steering and control of real and virtual objects without creating cyber sickness. The expected latency that would make these applications feasible is around 1 ms. Although current smartphones have touch screens as the main interface, future devices will integrate various other interfaces like haptic, visual and auditory input and feedback, which will provide a new way of interacting with online environment for applications in

virtual reality, healthcare, gaming, and sports, etc. These applications require real-time interactions with the user and any delay in the system will cause degradation to the user experience, thus latency is a crucial factor in 5G. This type of communication requires extremely low latency for applications like vehicle-to-vehicle communication. The requirement of low latency will also improve the user experience for currently existing applications such as multi-user gaming.

3.3 LOW ENERGY CONSUMPTION

The 5G networks are expected to support the IoT devices which are basically some sensors that gather information about an environment and transmit it to a central server. These devices are mostly low-power, low-cost devices with lifespans as long as several years. Since these devices are not always connected to the base station and are only switched on occasionally, their battery life cannot afford the process of synchronization with the base station every time, as the synchronization step costs more energy than that of actual data transmission. This specific case in IoT requires that the radio access technique for 5G support loose or no synchronization. Moreover, this type of service also puts constraints on the computational power for decoding, the length of header, and packet forwarding scheme, etc. With the increasing number of connected smart devices, the number of base stations required to support these devices will also escalate. Because of the deployment of small cells, the base station will be densified. This foreseeable trend demands the base stations to be energy efficient since even a small improvement in energy efficiency will translate to huge energy savings in large scale.

3.4 HIGH SCALABILITY

To support increasing amount of mobile devices that connect to the wireless network and communicate with each other, network scalability becomes an important factor in design of the next generation wireless communications network. The increase in number of devices is further aggravated by the myriad of IoT devices and vehicle-to-vehicle communication technologies that are expected to surge in the 5G cellular network. Consequently, a highly scalable network that can efficiently accommodate this upsurge in number of devices is required. High scalability is also critical to performance of current and emerging applications, such as the IoT services, autonomous vehicles, etc. In the case of autonomous vehicles, prompt communications among them at high traffic densities necessitate the scalability of cellular network. In fact, the scalability of a network requires full-scale upgrade in all network layers. On the physical layer, there should be enough frequency spectrum resources to support high volume of signaling and data transmission. The network infrastructure should also be able to control the transmitted power adaptively for channel estimation and to minimize interference. Scalability also influences the design of efficient media access control (MAC) protocols to accommodate large amounts of connected devices. Scheduling and multicasting protocols based on geographic locations of users can greatly reduce the latency and increase the spectral efficiency. At the network and transport layers, high scalability requires networks to deploy intelligent routing algorithms for huge groups of users to provide fast and reliable connections. For users with high mobility, the vehicular network should also satisfy the scalability by providing efficient and reliable handoffs along the directions of the moving routes, as well as designing dynamic routing algorithms based on the user movement prediction. The scalability in networks will be achieved by changes in all layers from radio access to core networks, using wireless software defined networks and network function virtualization.

3.5 IMPROVED CONNECTIVITY AND RELIABILITY

Apart from the aforementioned requirements, coverage and handover efficiency should also be improved for a better user experience, particularly when millimeter wave spectrum is exploited. With the increase in density of the base stations and the number of devices connected, as well as the introduction of femtocells and picocells, the number of handovers that the base station should handle will increase by at least two orders of magnitude. To support this demand, novel handover algorithms and techniques that provide improved coverage in cell edge areas are required. Another related issue is the authentication and privacy concerns related to the handover. The delay to contact the authentication server for each handover will be hundreds of milliseconds which would be intolerable for 5G applications. Also, given the use of higher frequency bands in millimeter wave, the transmission range of signals is greatly reduced. Hence, maintaining connectivity becomes a great challenge for 5G. For mission-critical services, the requirements on high reliability as well as connectivity should always be guaranteed.

3.6 IMPROVED SECURITY

The security aspect of wireless network recently attracts high attention, especially after 2015, when the applications of mobile payments and digital wallet became popular. In retrospect of the previous generations of systems, the general purpose of security is to protect basic connectivity and maintain user privacy. However, since the 5G system will ultimately face the dramatically increasing data traffic in the entire network, the requirement of security of 5G should not only be limited to providing trust worthy connectivity to users, but also improving the security on the

whole network, addressing concerns on authentication, authorization as well as accounting, developing novel encryption protocols, and safeguarding cloud computing and management activities. As the IoT will come to its prime time in 5G networks, the processes of authentication, authorization, and accounting for interconnected devices should be granted with fine grained protecting mechanisms. Network operators, device manufacturers, as well as standardization bodies should work together on designing services, products, and protocols that can substantially protect the users subscribed to the 5G wireless network. Most importantly, as the Internet has become one of the indispensable infrastructures of the society similar to power grids, there should be enhanced federal regulations on liabilities and obligations on wireless network security. The 10 enabling technologies will collaborate to shape the 5G network architecture. The radio access network architecture will be enhanced with the deployment of wireless software-defined networking, network function virtualization, ultra-densification, device-to-device communications, millimeter wave, massive MIMO, and new radio access techniques, while the core network will evolve with key roles played by wireless software-defined networking, network function virtualization, Internet of Things, green communications, big data and mobile cloud computing.

CHAPTER 4

CLUSTERING ALGORITHM

4.1 CLUSTERING

Clustering (aka Cluster analysis) is the process of grouping a set of objects in such a way that objects in the same group (called a cluster) have similar features (in some sense) to each other than to those in other groups (clusters). It is important to

organize all the UEs into clusters based on one or more attributes of comparison (metric).

Criteria	Affinity Propagation	K-mean	K-medoid
Initial condition	No	Yes	Yes
Termination condition	Not precise	Precise	Precise
Effect on size of data sets	Not good	Good	Not good
Handling dynamic data	No	Yes	Yes
Implementation	Simple	Simple	Complicated

Table 4.1. Comparison between different clustering algorithms [6]

4.2 CLUSTERING PARAMETERS AND METRICS

Each clustering algorithm uses different clustering parameters such as number of clusters, bandwidth, distance threshold, linkage, etc. or a combination of the mentioned.

Clustering algorithm	Parameters	Metric
Affinity propagation	Damping, sample preference	Graph distance
K-mean	Number of clusters	Distances between points
K-medoid	Number of clusters	Distances between points

Table 4.2 Clustering algorithm parameters and metrics

A major drawback of affinity propagation clustering is that it will not perform well in large-scale data sets and that of K-medoid is the complexity of its implementation.

[7] K means being one of the oldest algorithms is the most approachable and works well with small-scale and large-scale data sets equally.

Table 4.1 shows the comparison between different clustering algorithms and why K-means is more suitable comparatively for the UE VBS selection algorithm. UE VBS selection algorithm handles dynamic data as UEs are mobile nodes and the data sets can be huge as there may be multiple UEs at a given location at an instance.

4.3 K-MEANS CLUSTERING ALGORITHM

The K-means clustering algorithm is an unsupervised machine learning technique used to identify clusters of data objects in a dataset. Here, the data objects are UEs and the data set is location information. There are multiple clustering algorithms, but K-means is one of the oldest and most approachable. It is also important to cluster UEs into non-overlapping groups which can be achieved using K-means. K-means clustering algorithm uses distance (Euclidean) as the metric and number of clusters as the parameter. [5]

The steps involved in k-means clustering algorithm is given below-

- Specify number of clusters K.
- Initialize centroids by first shuffling the dataset and then randomly selecting K data points for the centroids without replacement.
- Keep iterating until there is no change to the centroids, i.e., assignment of data points to clusters isn't changing.
- Compute the sum of the squared distance between data points and all centroids using Euclidean distance formula.

$$d = \sum_{i=1}^n \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}$$

Where,

d = Euclidean distance

n = number of clusters

x_1, x_2, y_1, y_2 = UE coordinates

- Assign each data point to the closest cluster (centroid).
- Compute the centroids for the clusters by taking the average of all data points that belong to each cluster.

The optimum size of number of clusters (K) is extremely essential as it is the only parameter considered for K-means clustering algorithm. This can be determined by using Elbow method. To perform the elbow method, K-means is run several times with k value incremented for each iteration, and the SSE is recorded. The value of SSE takes a dip at a particular cluster size value and this is referred to as elbow. [7]

Fig 4.1 Plot of SSE vs Number of clusters

As number of clusters increases (k), SSE continues to decrease. The point where SSE takes a bend is the elbow point and at this point, the value of k can be used as the optimum cluster size.

CHAPTER 5

COMMUNICATION PARAMETERS

5.1 BATTERY DISCHARGE RATE

Battery power is one of the major factors in a wireless Ad hoc network. A node can transmit data to a longer distance only if it has sufficient battery power. Since most UEs are portable devices, they are not often reliable to withstand transmission of 5G signal for a long period of time. When a device's battery dies, the network functionality gets disrupted. [4], [9] Hence, the battery discharge rate of the eligible UE-VBSs is an important factor in the selection of a suitable VBS.

$$\text{Battery discharge rate} = \frac{\text{Capacity (mAh)}}{\text{Discharge time (h)}}$$

5.2 POWER RECEIVED

The Power received by each UE in a cluster from the BS is a very important communication parameter, as this decides how much power will be relayed to the other nodes in the cluster once it is assigned as a VBS. When a signal travels over a channel medium, the signal power tends to fade due to power dissipation with distance and effects of the propagation channel. [2]

The received power can be computed using the Log normal path loss model-

$$[P_L(d)]dB = [P_L(d_0)]dB + 10 n \log_{10} \left(\frac{d}{d_0} \right) + \chi$$

for $d_f \leq d_0 \leq d$ (1)

Where n is path loss exponent; χ is a Gaussian random variable; d is the distance between Tx and Rx.

$P_L(d_0)$ is reference path loss calculated using Frii's free space formula-

$$P_L(d_0) = P_r(d) = \frac{P_t G_t G_r \lambda^2}{4\pi^2 d^2 L} \quad \text{where} \quad G = \frac{4\pi A_e}{\lambda^2}$$

- P_t = Transmit Power
- $P_r(d)$ = Received Power at a distance 'd'
- G_t = Transmit antenna power gain
- G_r = Received antenna power gain
- λ = Wavelength
- $L \geq 1$, System loss factor not related to propagation
- D = Separation distance.

Environment	Path Loss Exponent
In building line-of-site	1.6 to 1.8
Free space	2
Obstructed in factories	2 to 3
Urban area cellular radio	2.7 to 3.5
Shadowed urban cellular radio	3 to 5
Obstructed in building	4 to 6

Table No. 5.1 Variation of PL in different environments

Path loss gives a measure of signal attenuation. It is usually measured in dB. It is defined as a difference between the transmitted antenna gains. The received power predicted by path loss models is influenced by:

- Reflection: Reflection occurs when the propagation waves impinge on objects with dimension larger than λ .

- **Diffraction:** Diffraction is caused by sharp irregularities in the path of radio waves. It leads to development of secondary wave fronts, bending of waves. It is caused by objects which are in order in λ . It depends on geometry of the objects, amplitude, phase and polarization of incident waves.
- **Scattering:** Scattering is caused by objects which are smaller than λ .

5.3 SINR

Signal to Interference plus Noise ratio is used to measure channel capacity in wireless communication systems. It is the measure of power of signal of interest divided by the sum of interference power from all interfering signals and power of background noise. If the background noise is zero or negligible, SINR reduces to SIR (Signal to Interference Ratio) and similarly if Interference is zero, SINR reduces to SNR (Signal to Noise Ratio). SINR has multiple important applications which include optimizing transmit power level for a target QOS, assisting with handoff decisions and dynamically adapting the data rate for wireless applications.

The signal-to-interference-plus-noise ratio (SINR) of a link from UE n to UE m is given by:

$$\gamma_{n,m} = \frac{h_{n,m} P_n \lambda r_{n,m}^{-\alpha}}{\sigma^2 + \sum_{\substack{t \in \Phi_m \\ t \neq n}} h_{t,m} P_t \lambda r_{t,m}^{-\alpha}},$$

where $h_{n,m}$ and $r_{n,m}$ are the fading power gain and distance of the link from UE n to UE m , respectively, P_n is the transmit power of UE n , λ is the frequency dependent pathloss, α is the pathloss distance exponent, m denotes the set of interferers to UE m , and σ^2 is the additive white Gaussian noise (AWGN) power. [3]

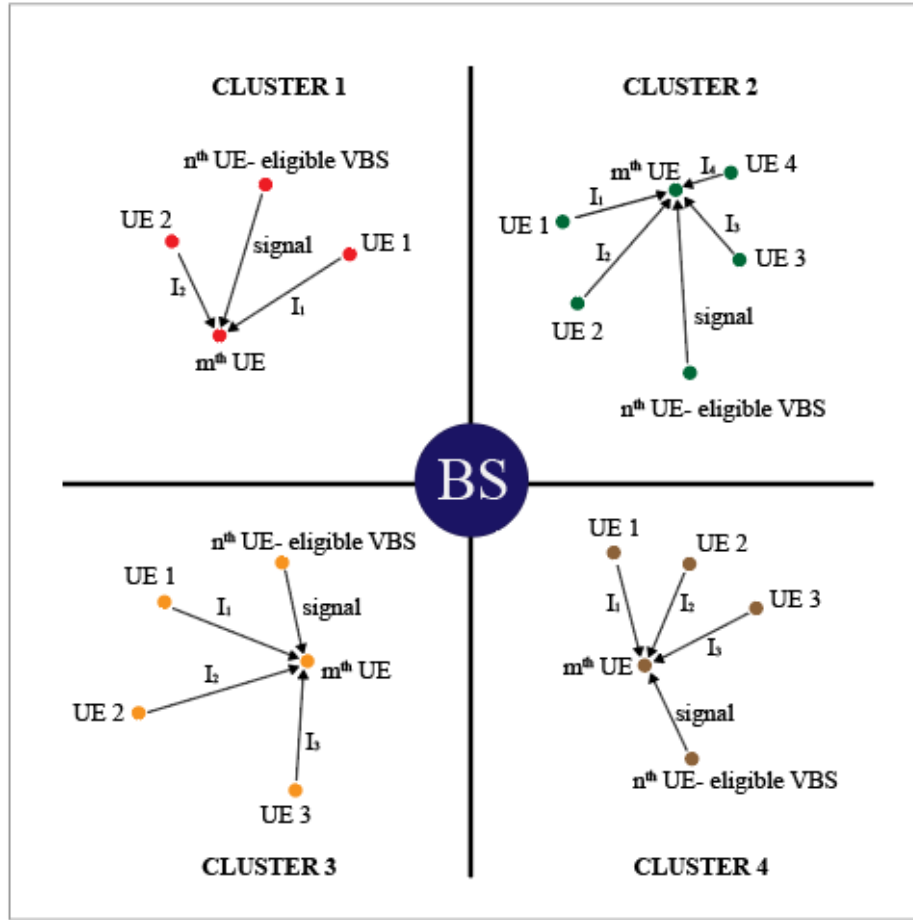

Fig. 5.3 Transmission of signal in the presence of interference

The above figure shows the transmission of downlink signal from the n^{th} UE (Eligible VBS) to m^{th} UE in the presence of interference from UE1, UE2, UE3 and so on, in each cluster.

5.4 OUTAGE PROBABILITY

Outage probability is defined as the point at which the received power value falls below the threshold (where the power value relates to the SINR within a cell).

$$\text{Outage Probability} = P(\text{SINR} \leq \lambda_{th})$$

5.5 THROUGHPUT

Throughput is the actual amount of data that is successfully sent/received over the communication link. Throughput can differ from bandwidth due to a range of technical issues, including latency, packet loss, jitter and more. Throughput is often associated with Channel capacity as it also determines the amount of data that is sent/received successfully in the communication channel. This can be computed using Shannon Capacity which is given by:

$$R = B \log_2 (1 + SINR) \text{ bps}$$

where R = Data rate

B = Channel Bandwidth

SINR = Signal to Interference plus Noise Ratio

CHAPTER 6

METHODOLOGY OF IMPLEMENTATION

Having discussed the clustering algorithms and communication parameters prominently used in our UE-VBS selection algorithm, we move on to deal with the methodology of implementation. The flowchart of implementation is shown in Figure 6.1.

6.1 BRIEF OVERVIEW

The location coordinates of UEs are initialized which denote the position of the UEs at a given time 't'. These UEs are mobile nodes and hence do not have a static

location for a long time, thus the UE VBSs have to be allocated dynamically w.r.t it's position at different instances.

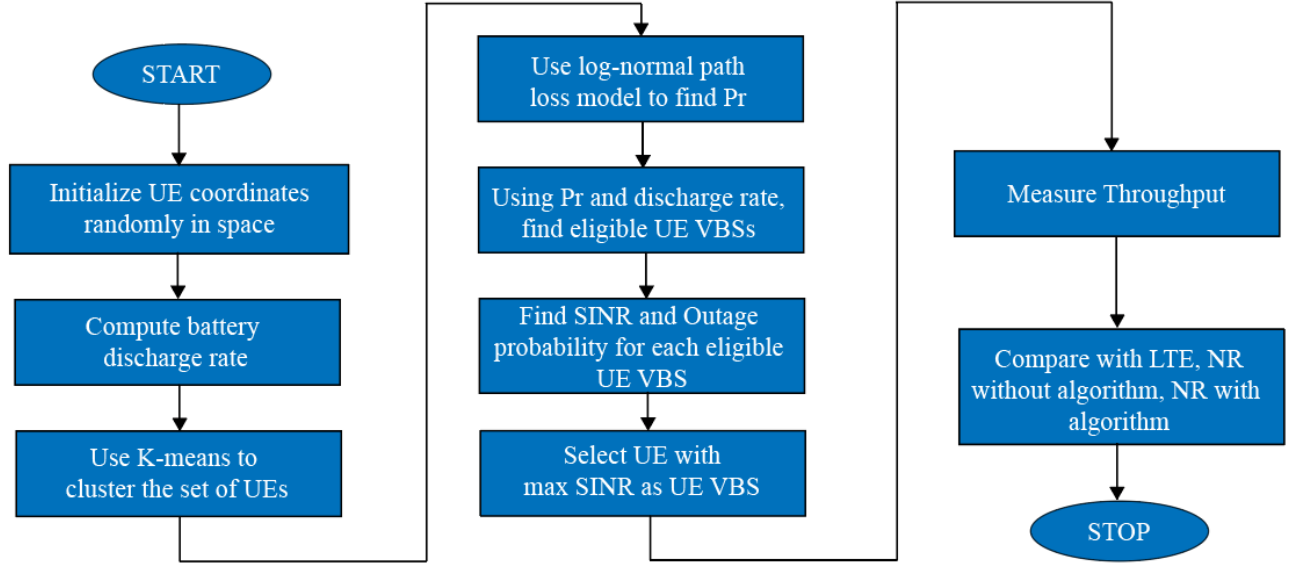

Fig. 6.1 Flowchart of implementation

The battery discharge rate is calculated for each UE using the formula mentioned in section 5.1. Each UE has to be organized into clusters based on their Euclidean distance adopting the K-means clustering algorithm. The cluster size depends on the number of UEs and its positions which again depends on the given data set. The optimal cluster size can be obtained by using Elbow point method. Once the UEs are organized into clusters, the received power of each UE from the BS is obtained using the log-normal path loss model.

Based on the battery discharge rate and received power, the eligible UE VBSs in each cluster are marked. The SINR and Outage probability of these eligible UE VBSs in each cluster are calculated and out of the eligible UE VBSs in a particular cluster, the UE with the highest SINR value is selected to act as the UE VBS for that

cluster. The throughput of the allocated UE VBS in each cluster is calculated using Shannon capacity theorem.

6.2 CLUSTERING IN A DYNAMIC ENVIRONMENT

The position of UEs are initialized as Cartesian pairs, i.e., (x, y) coordinates in space. The angle, speed and time intervals are initialized randomly to facilitate movement of UEs to deploy a dynamic selection environment. The UEs are mobile nodes and thus at various intervals, their positions and movements are dynamic. At a time t1, an UE, say UE1, can belong to cluster 1 but at time t2, it can belong to cluster 4. This is because clustering is done using K-means clustering algorithm which uses Euclidean distance to allocate UEs into different clusters.

The speed is randomly varied between 0 m/s to 10 m/s and angle between 10 to 350 degrees and these changes occur at a time interval of 20 s.

6.3 BATTERY DISCHARGE RATE CALCULATION

$$\text{Battery discharge rate} = \frac{\text{Capacity (mAh)}}{\text{Discharge time (h)}}$$

The battery discharge rate is calculated as the ratio of instantaneous battery life, which is a value between 4000 to 7000 (in mAh), to discharge time in hours, which is a value in the range of 1 to 15 hours. These values are assigned and calculated randomly.

In a real-time scenario, these values can be obtained from the battery design information of each node.

6.4 RECEIVED POWER CALCULATION

The received power of each UE from a BS is calculated using the log normal path loss model which is given below.

$$[P_L(d)]dB = [P_L(d_0)]dB + 10 n \log_{10} \left(\frac{d}{d_0} \right) + \chi$$

$$\text{for } d_f \leq d_0 \leq d \quad (1)$$

Where,

n is path loss exponent=4;

χ is a Gaussian random variable;

d is the distance between Tx and Rx.

$P_L(d_0)$ is reference path loss calculated using Frii's free space formula:

$$P_L(d_0) = P_r(d) = \frac{P_t G_t G_r \lambda^2}{4\pi^2 d^2 L} \quad \text{where} \quad G = \frac{4\pi A_e}{\lambda^2}$$

- P_t = Transmit Power
- $P_r(d)$ = Received Power at a distance 'd'
- G_t = Transmit antenna power gain
- G_r = Received antenna power gain
- λ = Wavelength
- $L \geq 1$, System loss factor not related to propagation
- d = Separation distance.

The values considered for the received power (P_r) calculation are:

Transmit antenna gain(G_t) = 1; Receiver antenna gain (G_r) = 1 (For simplicity)

Transmit Power (P_t)= 43 dBm (Generally in the range of 43-46 dBm)

Path loss exponent (L)= 4 (Obstructed in building- includes shadowing)

Frequency ($FR1$) = 5 GHz (5G frequency range; FR2- Transition of signal from indoor to outdoor is very poor)

Wavelength (λ) = 0.06 m

6.5 SINR CALCULATION

The signal-to-interference-plus-noise ratio (SINR) of a link from UE n to UE m is given by:

$$\gamma_{n,m} = \frac{h_{n,m} P_n \lambda r_{n,m}^{-\alpha}}{\sigma^2 + \sum_{\substack{t \in \Phi_m \\ t \neq n}} h_{t,m} P_t \lambda r_{t,m}^{-\alpha}},$$

where

$h_{n,m}$ = fading power gain = 0.4292 [10]

$r_{n,m}$ = distance of the link from UE n to UE m

P_n = transmit power of UE n (depends on distance of UE, etc.)

λ = frequency dependent pathloss = 4 (For outdoor communication, path loss is independent of frequency)

α = pathloss distance exponent= 4

m denotes the set of interferers to UE m , and σ^2 is the additive white Gaussian noise (AWGN) power. The AWGN power is assumed to be negligible as compared to the interference power and that the traffic follows a full buffer model.

6.6 OUTAGE PROBABILITY CALCULATION

The expected outage probability for a single-hop D2D link using DL resources is obtained as:

$$\mathbb{E}_R (P_{D2D,out}^{DL}) = 1 - \frac{N_{D2D} - 1}{N_{D2D} - 1 + \Omega \mathcal{B}(\zeta, \alpha)},$$

where $\Omega = 1 + \frac{\Lambda_{BS}}{\Lambda_{D2D}} \left(\frac{P_{BS}}{P_{D2D}} \right)^{\frac{2}{\alpha}}$ and P_{BS} is the power of BS.

Where,

Λ_{BS} is number density of Base Stations = $2/$ (Area of the cell)

Λ_{D2D} is the number density of UEs = (Number of UEs in one cluster-1)/ (Area of the cluster)

ζ is the average SINR of the chosen cluster.

6.7 THROUGHPUT CALCULATION

6.7.1 UE LEVEL

The throughput for individual UEs can be calculated using Shannon Capacity which is given by:

$$R = B \log_2 (1 + SINR) \text{ bps}$$

where

R = Data rate

B = Channel Bandwidth= 100 MHz for 5G and 20 MHz for LTE

SINR = Signal to Interference plus Noise Ratio

6.7.2 SYSTEM LEVEL

The entire system's throughput is obtained using the formula given below:

$$\overline{TP} = \sum_{i=1}^{c-size} B \log_2 (1 + \overline{SINR}_i)$$

where,

c-size = cluster size

$SINR_i$ = SINR of i^{th} cluster

\overline{SINR}_i = Average SINR of i^{th} cluster

The throughput value obtained from the above formula denotes the NR throughput using the UE VBS selection algorithm.

The throughput of NR without algorithm and that of LTE is compared with the results obtained using our algorithm and the conclusions are drawn. The UEs are mobile nodes, so when each time a UE moves, its Euclidean distance changes and therefore a UE can move in/out of different clusters at different instances, since clustering is done using Euclidean distance as the metric. Therefore, the allocation of UEs into clusters is done dynamically in real-time.

CHAPTER 7

RESULTS

7.1 POSITIONING OF UEs FOR CLUSTER SIZE 4

Fig 7.1 Position of UE's at time t1, t2 and t3

The UEs are positioned in a pseudo random manner at a time instant t1. After Δt seconds, the positions of the UEs are arbitrarily changed by assigning random velocity to each UE for two other time instances t2 ($t1 + \Delta t$) and t3 ($t1 + 2 \times \Delta t$).

Fig 7.2 Selection of UE VBS for cluster size 4, at time t1

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 4 at time instance t1.

Fig 7.3 Selection of UE VBS for cluster size 4, at time t2

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 4 at time instance t2.

Fig 7.4 Selection of UE VBS for cluster size 4, at time t3

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 4 at time instance t3.

7.2 PERFORMANCE ANALYSIS FOR VARIOUS CLUSTER SIZES

Fig 7.5 Selection of UE VBS for cluster size 2

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 2.

Fig 7.6 Throughput of UE VBS for cluster size 2

The average throughput for each cluster is computed using the Shannon-Hartley theorem for an UE VBS selected by the proposed algorithm against an UE VBS selected at random (and for an LTE base station) for cluster size 2.

Fig 7.7 Selection of UE VBS for cluster size 3

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 3.

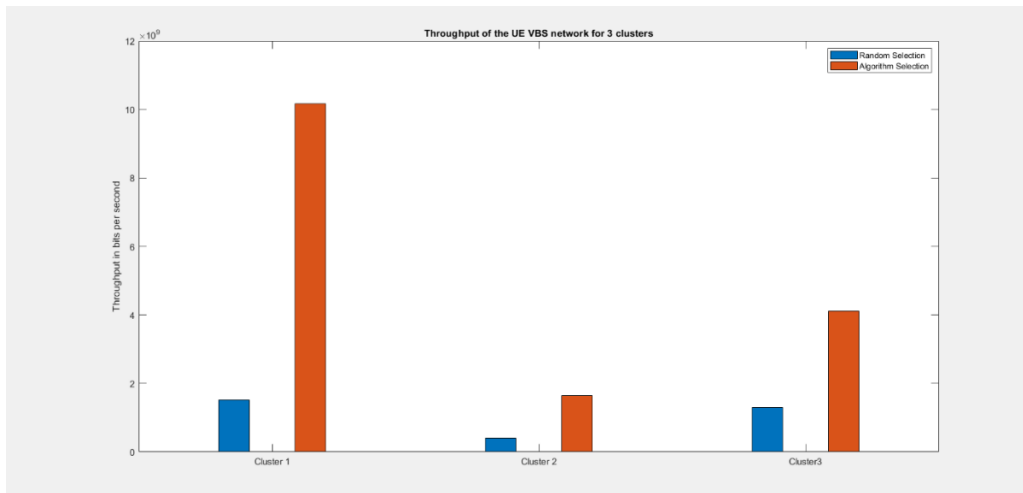

Fig 7.8 Throughput of UE VBS for cluster size 3

The average throughput for each cluster is computed using the Shannon-Hartley theorem for an UE VBS selected by the proposed algorithm against an UE VBS selected at random (and for an LTE base station) for cluster size 3.

Fig 7.9 Selection of UE VBS for cluster size 4

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 4.

Fig 7.10 Throughput of UE VBS for cluster size 4

The average throughput for each cluster is computed using the Shannon-Hartley theorem for an UE VBS selected by the proposed algorithm against an UE VBS selected at random (and for an LTE base station) for cluster size 4.

Fig 7.11 Selection of UE VBS for cluster size 5

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 5.

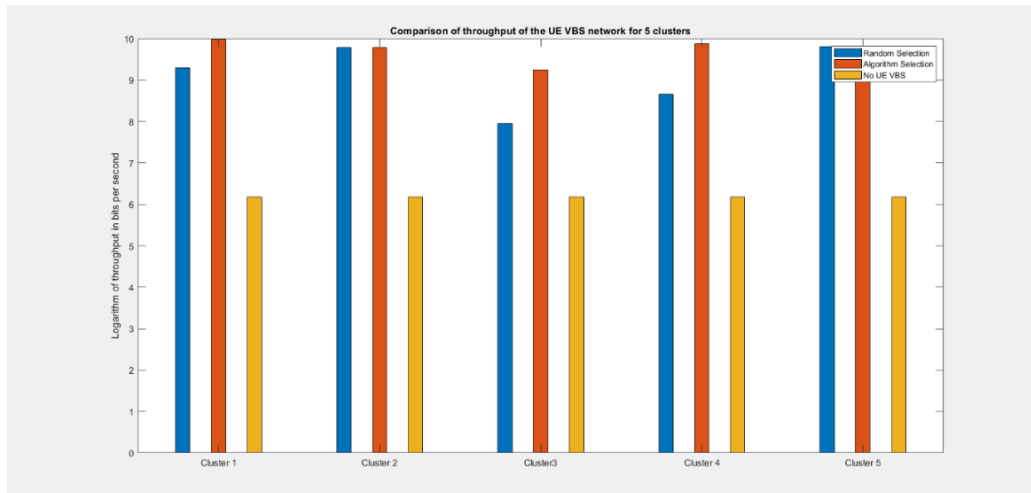

Fig 7.12 Throughput of UE VBS for cluster size 5

The average throughput for each cluster is computed using the Shannon-Hartley theorem for an UE VBS selected by the proposed algorithm against an UE VBS selected at random (and for an LTE base station) for cluster size 5.

Fig 7.13 Selection of UE VBS for cluster size 6

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 6.

Fig 7.14 Throughput of UE VBS for cluster size 6

The average throughput for each cluster is computed using the Shannon-Hartley theorem for an UE VBS selected by the proposed algorithm against an UE VBS selected at random (and for an LTE base station) for cluster size 6.

Fig 7.15 Selection of UE VBS for cluster size 7

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 7.

Fig 7.16 Throughput of UE VBS for cluster size 7

The average throughput for each cluster is computed using the Shannon-Hartley theorem for an UE VBS selected by the proposed algorithm against an UE VBS selected at random (and for an LTE base station) for cluster size 7.

Fig 7.17 Selection of UE VBS for cluster size 8

From each cluster, the algorithm selects an UE to act as a VBS using power received, battery discharge rate and SINR, for cluster size 7.

Fig 7.18 Throughput of UE VBS for cluster size 8

The average throughput for each cluster is computed using the Shannon-Hartley theorem for an UE VBS selected by the proposed algorithm against an UE VBS selected at random (and for an LTE base station) for cluster size 8.

7.3 SYSTEM THROUGHPUT INFERENCE

Fig 7.19 Average throughput for varying clusters

The average throughput for the system with different cluster sizes is plotted. Performance of the system with cluster size 2 is neglected since it might lead to underfitting. Since the availability of UE VBS in each cluster is dynamic, the cluster size can be chosen to fit the necessary requirements, ideally 4, 5 or 8 in this case.

Fig 7.20 Comparison of average throughput with LTE and NR with no UEVBS

The throughput of an LTE system and that of a 5G system with no UE VBS is plotted along with the throughput of various 5G UE VBS systems with varying cluster sizes,

above. It can be inferred that the usage of 5G UE VBSs shows a significantly better system performance than the other mentioned systems.

CHAPTER 8

CONCLUSION AND FUTURE SCOPE

8.1 GENERAL SUMMARY

Thus, UE Virtual Base Stations are dynamically selected among UEs to deal effectively with the non-stationary, non-uniform distribution of mobile traffic with respect to time and space domain. This concept is facilitated using K-means Clustering to split one macro cell into small cells. Communication parameters such as received power, battery discharge rate and SINR is used to select the best set of UE-VBSs to replace an overlay loaded SBS. Throughput is used to compare the performance of our selection algorithm, against the performance of a random selection algorithm. In some cases, the performance of a 4G network is measured against a 5G network with UE VBS. It is observed from the results that the proposed algorithm outperforms the 4G network and 5G network with random UE VBS selection.

8.2 FUTURE SCOPE

The project can be extended to include the phenomenon of co-channel interference from other base stations and UEs from other cells. The frequency range of the signals can be changed to the FR2 range of frequencies where concepts like Massive MIMO will play a major role in the selection of UE VBS.

The reliability of the UE VBS cannot be predicted with the current selection algorithm as any user might have malicious intent and can cause severe privacy risks for all the other UEs in the small cell. The information loss/theft due to the rogue UE VBS can be a criminal offence of the highest order. To avoid this, the Base Station should select the UE VBS in an intelligent manner with the help Artificial Intelligent tools.

The performance of the network using the selection algorithm can also be compared with other algorithms and other networks by measuring the energy efficiency and Quality of Service of the networks.
